```

0. Learning outcomes

This lab will teach you how 1) to read in data and reshape it so it matches your needs, and 2) to make different types of graphs that you need for data exploration and presentation purposes. It does so by reproducing the figures shown in Chapter 2 and more. The exercises, which will be more difficult than those in Lab 1, will typically involve variations on the figures shown in the text. You will work through reading in the different data sets and constructing the figures shown, or variants of them. It would be even better to work through reading in and making exploratory plots of your own data.

1. Reading data

Find the file called ‘seedpred.dat’: it’s in the right format (plain text, long format), so you can just read it in with

```
data = read.table("seedpred.dat", header = TRUE)
```

Add the variable available to the data frame by combining taken and remaining (using the \$ symbol):

```
data$available = data$taken + data$remaining
```

Pitfall #1: finding your file If R responds to your `read.table()` or `read.csv()` command with an error like

```
Error in file(file, "r") : unable to open connection In addition:
Warning message: cannot open file 'myfile.csv'
```

it means it can’t find your file, probably because it isn’t looking in the right place. By default, R’s working directory is the directory in which the R program starts up, which is (again by default) something like `C:/Program Files/R/rw2010/bin`. (R uses `/` as the [operating-system-independent] separator between directories in a file path.) If you are using Rstudio, go to ‘Session’ and click ‘Set working directory’. You can also use the `setwd()` command to set the working directory (`getwd()`

tells you what the current working directory is). While you could just throw everything on your desktop, it's good to get in the habit of setting up a separate working directory for different projects, so that your data files, metadata files, R script files, and so forth, are all in the same place. Depending on how you have gotten your data files onto your system (e.g. by downloading them from the web), Windows will sometimes hide or otherwise screw up the extension of your file (e.g. adding .txt to a file called `mydata.dat`). R needs to know the full name of the file, including the extension.

For example to set a working directory:

```
setwd("D:/Bolker/labs/")
```

Pitfall #2: checking number of fields The next potential problem is that R needs every line of your data file to have the same number of fields (variables). You may get an error like:

```
Error in read.table(file = file, header = header, sep = sep, quote  
= quote, : more columns than column names
```

or

```
Error in scan(file = file, what = what, sep = sep, quote = quote,  
dec = dec, : line 1 did not have 5 elements
```

If you need to check on the number of fields that R thinks you have on each line, use

```
count.fields("myfile.dat", sep=",")
```

(you can omit the `sep=","` argument if you have whitespace- rather than comma delimited data). If you are checking a long data file you can try

```
cf = count.fields("myfile.dat", sep=",")  
which(cf!=cf[1])
```

to get the line numbers with numbers of fields different from the first line. By default R will try to fill in what it sees as missing fields with NA (“not available”) values; this can be useful but can also hide errors. You can try

```
mydata <- read.csv("myfile.dat", fill = FALSE)
```

to turn off this behavior; if you don't have any missing fields at the end of lines in your data this should work.

If your file is a comma separated file, you can also use `read.csv`. This function has set some arguments to default, e.g. the separator is a comma in this case (`sep=","`)

1.1. Checking data

Here's the quickest way to check that all your variables have been classified correctly:

```
sapply(data, class)
```

```
##   species      tcum      tint remaining    taken available  
## "factor" "integer" "integer" "integer" "integer" "integer"
```

(this applies the `class()` command, which identifies the type of a variable, to each column in your data). Alternatively,

```
summary(data)
```

can be very helpful to get a glance of the characteristics of the data.

Non-numeric missing-variable strings (such as a star, *) will also make R misclassify. Use `na.strings` in your `read.table()` command:

```
mydata <- read.table("mydata.dat", na.strings = "*")
```

(you can specify more than one value with (e.g.) `na.strings=c(" ", "***", "bad", "-9999")`).

Exercise 1.1: Try out `head()`, `summary()` and `str()` on data; make sure you understand the results.

1.2 Reshaping data

It's hard to give an example of reshaping the seed predation data set because we have different numbers of observations for each species - thus, the data won't fit nicely into a rectangular format with (say) all observations from each species on the same line. However, as in the chapter text I can just make up a data frame and reshape it. Here are the commands to generate the data frame I used as an example in the text (I use `LETTERS`, a built-in vector of the capitalized letters of the alphabet, and `runif()`, which picks a specified number of random numbers from a uniform distribution between 0 and 1. The command `round(x,3)` rounds `x` to 3 digits after the decimal place.):

```
loc = factor(rep(LETTERS[1:3],2))  
day = factor(rep(1:2,each=3))  
val = round(runif(6),3)  
d = data.frame(loc,day,val)
```

This data set is stored in long format. To go to wide format, we first need to (install and) load the library `reshape2`. In Lab 1 you learned how to install packages. You

can load a package by `library()` or `require()`. Thus to use an additional package it must be (i) installed on your machine (with `install.packages()`) or through the menu system and (ii) loaded in your current R session (with `library()`):

```
library(reshape2)
d2 = dcast(d, loc ~ day )
```

```
## Using val as value column: use value.var to override.
```

```
d2
```

```
##   loc      1      2
## 1   A 0.966 0.561
## 2   B 0.590 0.426
## 3   C 0.750 0.876
```

`loc~day` specifies that `loc` will be used as rows and `day` will be put into columns.

To go back to long format, we simply write:

```
melt(d2, variable.name="day")
```

By specifying the `variable.name` to `day`, we put the columns (1 and 2) into a new column called `day`. The column in which the values are stored can be set by using the argument `value.name`

```
melt(d2, variable.name="day", value.name="val")
```

```
## Using loc as id variables
```

```
##   loc day   val
## 1   A   1 0.966
## 2   B   1 0.590
## 3   C   1 0.750
## 4   A   2 0.561
## 5   B   2 0.426
## 6   C   2 0.876
```

Exercise 1.2: Add a new column `month` (consisting of two levels) to `d` in which `loc` and `day` are nested and reshape to wide format and back to long format. The long format is what we commonly use in statistics.

```
loc = factor(rep(LETTERS[1:3],4))
month = factor(rep(1:2,each=6))
day = factor(rep(1:2,each=3))
val = round(runif(6),3)
d1 = data.frame(loc,month,day,val)
```

```

d3 = dcast(d1,loc~month+day)

## Using val as value column: use value.var to override.
melt(d3,variable.name="month_day")

## Using loc as id variables

##      loc month_day value
## 1     A         1_1 0.563
## 2     B         1_1 0.665
## 3     C         1_1 0.598
## 4     A         1_2 0.951
## 5     B         1_2 0.584
## 6     C         1_2 0.783
## 7     A         2_1 0.563
## 8     B         2_1 0.665
## 9     C         2_1 0.598
## 10    A         2_2 0.951
## 11    B         2_2 0.584
## 12    C         2_2 0.783

```

1.3 Advanced data types (Time permitting)

While you can usually get by coding data in not quite the right way - for example, coding dates as numeric values or categorical variables as strings - R tries to “do the right thing” with your data, and it is more likely to do the right thing the more it knows about how your data are structured.

Strings instead of factors Sometimes R’s default of assigning factors is not what you want: if your strings are unique identifiers (e.g. if you have a code for observations that combines the date and location of sampling, and each location combination is only sampled once on a given date) then R’s strategy of coding unique levels as integers and then associating a label with integers will waste space and add confusion. If all of your non-numeric variables should be treated as character strings rather than factors, you can just specify `as.is=TRUE`; if you want specific columns to be left “as is” you can specify them by number or column name. For example, these two commands have the same result:

```

data2 = read.table("seedpred.dat", header = TRUE, as.is = "Species")
data2 = read.table("seedpred.dat", header = TRUE, as.is = 1)
apply(data2, class)

```

(use `c()` - e.g. `c("name1","name2")` or `c(1,3)` - to specify more than one column).

You can also use the `colClasses="character"` argument to `read.table()` to specify that a particular column should be converted to type character:

```
data2 = read.table("seedpred.dat", header = TRUE, colClasses = c("character",
+ rep("numeric", 4)))
```

again has the same results as the commands above. To convert factors back to strings *after* you have read them into R, use `as.character()`.

```
data2 = read.table("seedpred.dat", header = TRUE)
sapply(data2, class)
```

```
data2$species = as.character(data2$species)
sapply(data2, class)
```

Factors instead of numeric values In contrast, sometimes you have numeric labels for data that are really categorical values - for example if your sites or species have integer codes (often data sets will have redundant information in them, e.g. both a species name and a species code number). It's best to specify appropriate data types, so use `colClasses` to force R to treat the data as a factor. For example, if we wanted to make `tcum` a factor instead of a numeric variable:

```
data2 = read.table("seedpred.dat", header = TRUE, colClasses = c(rep("factor",
2), rep("numeric", 3)))
sapply(data2, class)
```

n.b.: by default, R sets the order of the factor levels alphabetically. You can find out the levels and their order in a factor `f` with `levels(f)`. If you want your levels ordered in some other way (e.g. site names in order along some transect), you need to specify this explicitly. Most confusingly, R will sort strings in alphabetic order too, even if they represent numbers. This is OK:

```
f = factor(1:10)
levels(f)
```

```
## [1] "1" "2" "3" "4" "5" "6" "7" "8" "9" "10"
```

but this is not, since we explicitly tell R to treat the numbers as characters (this can happen by accident in some contexts):

```
f = factor(as.character(1:10))
levels(f)
```

```
## [1] "1" "10" "2" "3" "4" "5" "6" "7" "8" "9"
```

In a list of numbers from 1 to 10, “10” comes after “1” but before “2” ... You can fix the levels by using the `levels` argument in `factor()` to tell R explicitly what

you want it to do, e.g.:

```
f = factor(as.character(1:10), levels = 1:10)
x = c("north", "middle", "south")
f = factor(x, levels = c("far_north", "north", "middle", "south"))
```

so that the levels come out ordered geographically rather than alphabetically. Sometimes your data contain a subset of integer values in a range, but you want to make sure the levels of the factor you construct include all of the values in the range, not just the ones in your data. Use levels again:

```
f = factor(c(3, 3, 5, 6, 7, 8, 10), levels = 3:10)
```

Finally, you may want to get rid of levels that were included in a previous factor but are no longer relevant:

```
f = factor(c("a", "b", "c", "d"))
f2 = f[1:2]
levels(f2)
```

```
## [1] "a" "b" "c" "d"
```

```
f2 = factor(as.character(f2))
levels(f2)
```

```
## [1] "a" "b"
```

For more complicated operations with `factor()`, use the `recode()` function in the `car` package. **Exercise 1.3** : Illustrate the effects of the levels command by plotting the factor `f=factor(c(3,3,5,6,7,8,10))` as created with and without intermediate levels. For an extra challenge, draw them as two side-by-side subplots. (Use `par(mfrow=c(1,1))` to restore a full plot window.)

Dates Dates and times can be tricky in R, but you can (and should) handle your dates as type `Date` within ‘R rather than messing around with Julian days (i.e., days since the beginning of the year) or maintaining separate variables for day/month/year.

You can use `colClasses="Date"` within `read.table()` to read in dates directly from a file, but only if your dates are in four-digit-year/month/day (e.g. 2005/08/16 or 2005-08-16) format; otherwise R will either butcher your dates or complain

```
Error in fromchar(x) : character string is not in a standard unambiguous format
```

If your dates are in another format in a single column, read them in as character strings (`colClasses="character"` or using `as.is`) and then use `as.Date()`, which

uses a very flexible format argument to convert character formats to dates:

```
as.Date(c("1jan1960", "2jan1960", "31mar1960", "30jul1960"),
        format = "%d%b%Y")
```

```
## [1] "1960-01-01" "1960-01-02" "1960-03-31" "1960-07-30"
```

```
as.Date(c("02/27/92", "02/27/92", "01/14/92", "02/28/92", "02/01/92"),
        format = "%m/%d/%y")
```

```
## [1] "1992-02-27" "1992-02-27" "1992-01-14" "1992-02-28" "1992-02-01"
```

The most useful format codes are %m for month number, %d for day of month, %j% for Julian date (day of year), %y% for two-digit year (dangerous for dates before 1970!) and %Y% for four-digit year; see ?strptime for many more details. If you have your dates as separate (numeric) day, month, and year columns, you actually have to squash them together into a character format (with paste(), using sep="/" to specify that the values should be separated by a slash) and then convert them to dates:

```
year = c(2004,2004,2004,2005)
month = c(10,11,12,1)
day = c(20,18,28,17)
datestr = paste(year,month,day,sep="/")
date = as.Date(datestr)
date
```

```
## [1] "2004-10-20" "2004-11-18" "2004-12-28" "2005-01-17"
```

When you want to split a date to month, year and day, you can use 'strsplit':

```
date.c = as.character(date)
date.char = strsplit(date.c, "-" )
```

Which you subsequently can turn in to multiple columns through matrix:

```
dat.mat = matrix(unlist(date.char), ncol=3, byrow=TRUE)
```

Although R prints the dates in date out so they look like a vector of character strings, they are really dates: class(date) will give you the answer "Date". Note that when using the dat.mat these are characters.

Pitfall #2 quotation marks in character variables If you have character strings in your data set with apostrophes or quotation marks embedded in them, you have to get R to ignore them. I used a data set recently that contained lines like this: Western Canyon|valley|Santa Cruz|313120N|1103145W'Donnell Canyon

I used

```
data3 = read.table("datafile", sep = "|", quote = "")
```

to tell R that | was the separator between fields and that it should ignore all apostrophes/single quotations/double quotations in the data set and just read them as part of a string.

1.4 Accessing data

To access individual variables within your data set use `mydata$varname` or `mydata[,n]` or `mydata["varname"]` where `n` is the column number and `varname` is the variable name you want. You can also use `attach(mydata)` to set things up so that you can refer to the variable names alone (e.g. `varname` rather than `mydata$varname`). However, **beware**: if you then modify a variable, you can end up with two copies of it: one (modified) is a local variable called `varname`, the other (original) is a column in the data frame called `varname`: **it's probably better not to attach a data set, or only until after you've finished cleaning and modifying it**. Furthermore, if you have already created a variable called `varname`, R will find it before it finds the version of `varname` that is part of your data set. Attaching multiple copies of a data set is a good way to get confused: try to remember to `detach(mydata)` when you're done.

Here some examples to get the column with name 'species'

```
data["species"]
data[,1]
data$species # recommended! You explicitly define the dataframe and name of the column
```

To access data that are built in to R or included in an R package (which you probably won't need to do often), say

```
data(dataset)
```

(`data()` by itself will list all available data sets.)

2. Exploratory graphics

Below we will show you a diversity of possible graphs that you can produce in R. Graphics are really important to explore the data that you collected and want to analyse. A good data exploration improves the efficiency of your statistical analysis as you will have expectations how relations between variables look like. We show you how to make the graphics using the base plotting functions in R, even though specialized packages exist to make particular plots. In addition, we will show you how to make those graphs in `ggplot2` package. The `ggplot2` package

is very popular as it can create basically any type of graph without much effort. Note that in ggplot2 the ‘grammar’ to produce a graph is different from how the other graphs in R are build.

2.1 Bubble plot

Sometimes you have multiple variables in the dataset that you want to explore simultaneously. For example, you want to superimpose information on how often certain combinations of the number seeds available versus the number of seeds taken occur. For this a bubble or jitter plot may be useful. The function `jitter` adds small noise to a numeric vector which makes that observations that have the same combination of seeds available and taken are plotted at a slightly different location.

```
plot(jitter(taken)~jitter(available),xlab="Seeds available",  
     ylab="Seeds taken",data=data)
```

The bubble plot is a normal plot with the size of the points representing the number of observations for a given combination of seeds available and seeds taken.

To get this information we first need to make a summary table which we can get through:

```
t1 = table(data$available, data$taken)
```

This table needs to be changed to a long format in order to be useful for the plotting command. Change the table to a long format with seeds available and seeds taken as columns. Note that we are melting a 2-d array (see ?melt.array)

```
t2 = melt(t1, varnames=c("Seeds available", "Seeds taken"),
          value.name="val")
```

Now we can make a plot with the size of the bubbles proportional for the number of observations.

```
plot(`Seeds taken` ~ `Seeds available`, data=t2, cex=val)
```

The argument `cex` controls the size of the points. As you see the size of the bubbles are bit too large, so we need to adjust it. In addition, we need to adjust the scaling of the axis.

```
plot(`Seeds taken` ~ `Seeds available`, data=t2, cex=log(val)*2,
      xlim = c(0.3, 5.8), ylim=c(-0.5, 5.5))
```

In ggplot this can be done as follows

```
library(ggplot2)
ggplot(data=t2)+
  geom_point(aes(x = `Seeds available`, y = `Seeds taken`,
                 size = log(val)/2))+
  ylab("Seeds taken")+
  xlab("Seeds available")
```

```
## Warning in sqrt(x): NaNs produced
```

```
## Warning: Removed 10 rows containing missing values (geom_point).
```

In `ggplot2` you need to specify the dataset the variables come from. You do this through `data=...`, a specification of type of plot, a point plot can be specified through `geom_point`, a specification of the aesthetics (`aes(x...,y...)`) determines what is plotted on the axes of the point plot. If data is specified in the `ggplot` statement, it means that all plotting commands below `ggplot(...)+` use that dataframe as reference. If the size command is put inside the `aes` then size is dependent on some variable, if put outside the `aes` it requires a single value (similarly for e.g. `colour`, `linetype` and `shape`). New commands can be added to the first statement (`ggplot`) by adding a `+` after each line. If a column name contains a space you can refer to it by putting it between backticks: ...

We could add the number of observations to the plot (`plot`) using the command `text`. The function `text` needs at least three arguments, the x position and the y position of the text and the text to be printed at this position. `text` allows vectors for each of those arguments. Therefore we can write:

```
plot(`Seeds taken` ~ `Seeds available`, data=t2, cex=log(val)*2,
      xlim = c(0.3,5.8), ylim=c(-0.5,5.5))
text(t2[,1], t2[,2], t2[,3])
```

Exercise 2.1 Change the size of the printed numbers and remove the zeros from the graph.

Exercise 2.2: In general, you can specify plotting characters and colors in parallel with your data, so that different points get plotted with different plotting characters and colors. For example:

```
x = 1:10
col_vec = rep(1:2, length = 10)
pch_vec = rep(1:2, each = 5)
plot(x, col = col_vec, pch = pch_vec)
```

To use `col_vec` and `pch_vec` in `ggplot2` we need to make them factors

```
ggplot()+  
  geom_point(aes(x=x,y=x,shape=as.factor(pch_vec),colour=as.factor(col_vec)))
```

2.1 Bar plot (with error bars)

The command to produce the barplot (Figure 3) was:

```
barplot(t(log10(t1 + 1)), beside = TRUE, legend = TRUE, xlab = "Available",
  ylab = "log10(1+# observations)")
op = par(xpd = TRUE)
text(34.5, 3.05, "Number taken")
```

```
par(op)
```

Alternatively through `ggplot`

```
ggplot(data=t2)+
  geom_bar(aes(x=`Seeds available`,y=log10(val+1),
              fill=as.factor(`Seeds taken`)),
           stat="identity",position=position_dodge())
```

Again through `aes` we specify what is on the `x` and `y`. Through `fill` we subdivide the bars by the values in `taken`. `stat=identity` expresses that the values assigned to `y` will be used (compare `stat="count"`). Through specifying `position_dodge()` bars are printed side by side instead of stacked bars (`position_fill()`).

More impressively, the `ggplot` package can automatically plot a barplot of a three-way cross-tabulation (one barplot per species): try

```
t1.species = table(data$available,data$remaining,data$species)
t1.species = melt(t1.species,varnames=c("Seeds available","Seeds taken",
                                         "species"),value.name="val")

ggplot(data=t1.species)+
  geom_bar(aes(x=`Seeds available`,y=log10(val+1),
              fill=as.factor(`Seeds taken`)),stat="identity",
          position=position_dodge())+
  facet_wrap(~species)+
  coord_flip()
```

with `facet_wrap` a sequence of panels is made as specified by the variable behind the `~`. The `coord_flip` rotates the plot.

Exercise 2.2: Restricting your analysis to only the observations with 5 seeds available, create a barplot showing the distribution of number of seeds taken broken down by species. Choose whether you do this with `ggplot2` or through the base `plot` function.

To add error bars to the barplot, one needs to calculate the standard error of the means. We want to plot the standard error on top of the fraction seeds taken.

First, compute the fraction taken:

```
data$frac_taken = data$taken/data$available
```

Computing the mean fraction taken for each number of seeds available, using the `tapply()` function: `tapply()` (“table apply”, pronounced “t apply”), is an extension of the `table()` function; it splits a specified vector into groups according to the factors provided, then applies a function (e.g. `mean()` or `sd()`) to each group. This idea of applying a function to a set of objects is a very general, very powerful idea in data manipulation with R; in due course we’ll learn about `apply()` (apply a function to rows and columns of matrices), `lapply()` (apply a function to lists), `sapply()` (apply a function to lists and simplify), and `mapply()` (apply a function to multiple lists). For the present, though,

```
mean_frac_by_avail = tapply(data$frac_taken, data$available, mean)
```

computes the mean of `frac_taken` for each group defined by a different value of `available` (R automatically converts `available` into a factor temporarily for this purpose). If you want to compute the mean by group for more than one variable in a data set, use `aggregate()`. We can also calculate the standard errors, $\frac{\sigma}{\sqrt{(n)}}$:

```
n_by_avail = table(data$available)
se_by_avail = tapply(data$frac_taken, data$available, sd)/
               sqrt(n_by_avail)
```

First we plot a barplot after which we add arrows with an angle of 90 degrees. To position the error bars at the middle of the bars we need to retrieve those positions from the barplot command. This can be done through assigning a name `bara` to the barplot object and using those positions as x coordinates.

```
bara = barplot(mean_frac_by_avail,ylim=c(0,0.09))
# hack: we draw arrows but with very special "arrowheads"
arrows(bara[,1],mean_frac_by_avail-se_by_avail,bara[,1],
       mean_frac_by_avail+se_by_avail, length=0.05, angle=90, code=3)
```

With `ggplot2` this is possible through the following syntax. Note that there is

a convenient function, called `summarySE` in the `Rmisc` package to compute the means and se:

```
library(Rmisc)

## Loading required package: lattice
## Loading required package: plyr

sum.data = summarySE(data,measurevar= "frac_taken",groupvars=c("available"))
pd = position_dodge(0)
ggplot(aes(x=available,y=frac_taken),data=sum.data)+
  geom_bar(stat="identity")+
  geom_errorbar(aes(ymin=frac_taken-se, ymax=frac_taken+se),
               stat="identity", position=pd)
```

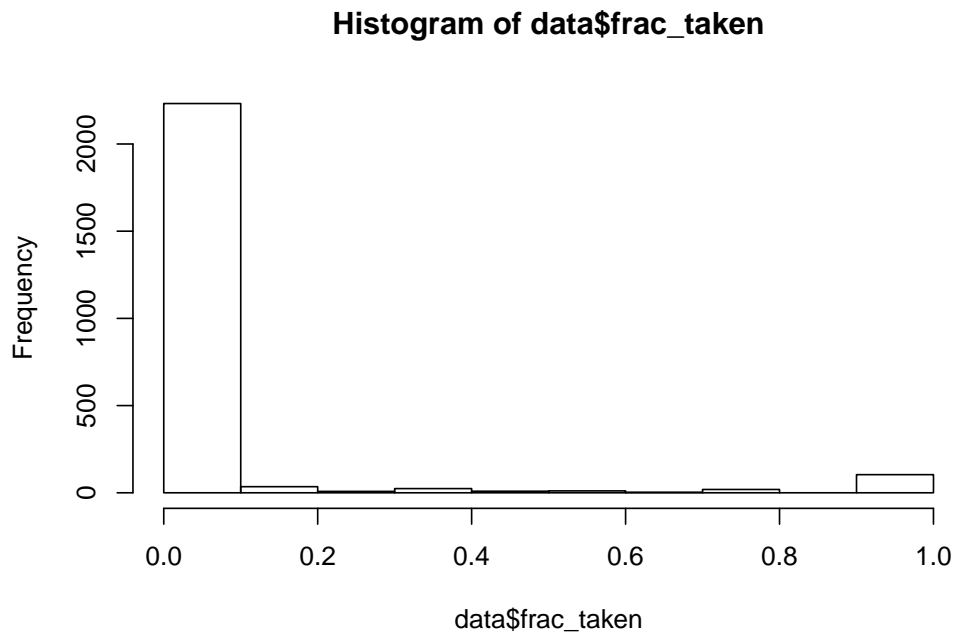

Make sure that the data reference is in the `ggplot()` function so all other functions such as `geom_bar` and `geom_errorbar` make use of the same `data.frame`.

2.4 Histogram by species

To make a histogram we can use the function `hist`:

```
hist(data$frac_taken)
```

To draw a histogram per species, we need to split the data into a list with each element representing a species.

```
data.s = split(data$frac_taken,list(data$species))
```

Next, we use `sapply` to plot the histograms.

```
par(mfrow=c(4,2),oma=c(0,0,0,0),mar=c(4,4,0.1,0.1))
sapply(data.s,hist,main="")
# or equivalently
for (i in 1:8){
  hist(data.s[[i]],main="")
}
```

With `ggplot2` you can get the frequencies less easily, so will be plot the counts

```
ggplot(data=data)+
  geom_bar(aes(x=frac_taken),stat="count")+
  facet_wrap(~ species)
```

```
ggplot(data=data,aes(x=frac_taken))+
  geom_histogram(aes(y = ..density..))+
  facet_wrap(~species)
```

`stat_bin()` using `bins = 30`. Pick better value with `binwidth`.

3. Measles Data

I'm going to clear the workspace (`rm(list=ls())` lists all the objects in the workspace with `ls()` and then uses `rm()` to remove them. It is recommend to have this code at the top of your script, so every time you start working on the script you are sure the memory is cleared. You can also Clear workspace from the menu (in Rstudio the little brush in the topright panel)) and read in the measles data, which are space separated and have a header:

```
rm(list = ls())
data = read.table("ewcitmeas.dat", header = TRUE, na.strings = "*")
```

year, mon, and day were read in as integers: I'll create a date variable as described above. For convenience, I'm also defining a variable with the city names.

```
date = as.Date(paste(data$year + 1900, data$mon, data$day, sep = "/"))
city_names = colnames(data)[4:10]
```

Later on it will be useful to have the data in long format. It's easiest to do use `melt` for this purpose. Note that only need to select the appropriate columns to melt (i.e. 4-11).

```
library(reshape2)
data= cbind(data,date)
data_long = melt(data[,4:11],id.vars=8,variable.name = "city",value.name="incidence")
```

3.1 Multiple-line plots

We can make a plot with multiple lines as follows. We first setup the plotting region using `plot` followed by the function `lines` to add lines to the existing plot. Note that in the plotting command `type="l"` is used to specify that lines are drawn instead of point (`type="p"`, the default). A legend can be added by adding the function `legend`

```
data_long$s = split(data_long,data_long$city)
plot(incidence ~ date,col=1,type="l",data=data_long[data_long$city == "London",])
unique.city = unique(data_long$city)
for (i in 2:length(unique.city)){
  lines(incidence ~ date,type="l",
        data=data_long[data_long$city == unique.city[i],],col=i)
}
legend("topright",legend=unique.city,col=1:8,lty=1)
```

With `ggplot2` we specify

```
ggplot() +
  geom_line(aes(x=date,y=incidence, colour=city),data=data_long)
```

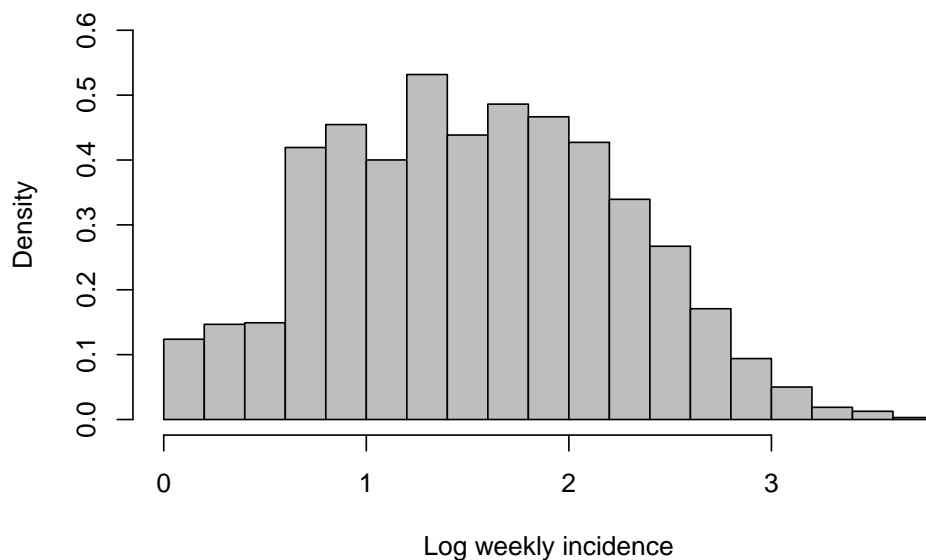

3.2 Histogram and density plots

I'll start by just collapsing all the incidence data into a single, logged, non-NA vector (in this case I have to use `c(as.matrix(x))` to collapse the data and remove all of the data frame information):

```
allvals = na.omit(c(as.matrix(data[, 4:10])))
logvals = log10(1 + allvals)
```

The histogram (`hist()` command is fairly easy: the only tricks are to leave room for the other lines that will go on the plot by setting the y limits with `ylim`, and to specify that we want the data plotted as relative frequencies, not numbers of counts (`freq=FALSE` or `prob=TRUE`). This option tells R to divide by total number of counts and then by the bin width, so that the area covered by all the bars adds up to 1; this scaling makes the vertical scale of the histogram compatible with a density plot, or among different histograms with different number of counts or bin widths (?? include in chapter ??).

```
hist(logvals, col = "gray", main = "", xlab = "Log weekly incidence",
     ylab = "Density", freq = FALSE, ylim = c(0, 0.6))
```

Adding lines for the density is straightforward, since R knows what to do with a density object - in general, the lines command just adds lines to a plot.

```
lines(density(logvals), lwd = 2)
lines(density(logvals, adjust = 0.5), lwd = 2, lty = 2)
```

With ggplot2 we specify:

```
ggplot()+
  geom_histogram(aes(x=logvals,y=..density..))+
  geom_density(aes(x=logvals,y=..density..))
```

```
## `stat_bin()` using `bins = 30`. Pick better value with `binwidth`.
```

3.3 Scaling data

Scaling the incidence in each city by the population size, or by the mean or maximum incidence in that city, begins to get us into some non-trivial data manipulation. This process may actually be easier in the wide format. Several useful commands: * `rowMeans()`, `rowSums()`, `colMeans()`, and `colSums()` will compute the means or sums of columns efficiently. In this case we would do something like `colMeans(data[,4:10])` to get the mean incidence for each city.

- `apply()` is the more general command for running some command on each of a set of rows or columns. When you look at the help for `apply()` you'll see an argument called `MARGIN`, which specifies whether you want to operate on rows (1) or columns (2). For example, `apply(data[,4:10],1,mean)` is the equivalent of `rowMeans(data[,4:10])`, but we can also easily say (e.g.) `apply(data[,4:10],1,max)` to get the maxima instead. Later, when you've gotten practice defining your own functions, you can apply any function - not just R's built-in functions.
- `scale()` is a function for subtracting and dividing specified amounts out of the columns of a matrix. It is fairly flexible: `scale(x,center=TRUE,scale=TRUE)` will center by subtracting the means and then scale by dividing by the

standard errors of the columns. Fairly obviously, setting either to FALSE will turn off that part of the operation. You can also specify a vector for either center or scale, in which case `scale()` will subtract or divide the columns by those vectors instead.

Exercise 3.1: figure out how to use `apply()` and `scale()` to scale all columns so they have a minimum of 0 and a maximum of 1 (hint: subtract the minimum and divide by (max-min)).

3.4 Box-and-whisker and violin plots

By this time, box-and-whisker and violin plots will (I hope) seem easy. Since the labels get a little crowded (R is not really sophisticated about dealing with axis labels-crowded labels), I'll use the `substr()` (substring) command to abbreviate each city's name to its first three letters.

```
city_abbr = substr(city_names, 1, 3)
```

The `boxplot()` command uses a formula - the variable before the `~` is the data and the variable after it is the factor to use to split the data up.

```
boxplot(log10(1 + incidence) ~ city, data = data_long, ylab = "Log(incidence+1)",  
names = city_abbr)
```

Or through `ggplot`

```
ggplot(data=data_long)+  
  geom_boxplot((aes(x=city,y=log10(incidence+1))))
```

If I want to make a violin plot, you can specify:

```
ggplot(data=data_long)+  
  geom_violin((aes(x=city,y=log10(incidence+1))))
```

4. Continuous data

First let's make sure the earthquake data are accessible:

```
data(quakes)
```

Luckily, most of the plots I drew in this section are fairly automatic. To draw a scatterplot matrix, just use `pairs()` (base):

```
pairs(quakes, pch = ".")
```

(`pch="."` marks the data with a single-pixel point, which is handy if you are fortunate enough to have a really big data set).

Exercise 4.1*: generate three new plots based on one of the data sets in this lab, or on your own data.
